

Introduction

Multiagent Pathfinding (MAPF) aims to facilitate efficient coordination between multiple mobile robots in a finite closed environment. These robot “agents” must navigate from their starting locations to their respective goals using the most efficient route that results in no conflicts with other agents or obstacles.

Objective & Impact of Research

Professor Nora Ayanian ACT Lab is developing algorithms for the coordination of multiple robots to complete automated tasks more efficiently. This would help make such teams of robots more commonplace in industry and possibly even in everyday life.

Currently, a popular application of MAPF is in warehousing, such as in Amazon’s Colorado facility, where human workers load packages onto robots, along with the corresponding destination within the warehouse. Each of the robots must find the shortest path to their destinations while predicting and avoiding any possible conflicts with other robots or obstacles.¹

that allows the human workers to rely more on these robots, reducing the physical and mental strain that often comes with the repetitive and physically demanding nature of such jobs.

Methods

- Before exploring MAPF, I first implemented Single-Agent Pathfinding (SAPF) algorithms like A* using Python and used Matplotlib to visualize the results (Fig. 2).
- Though A* is a SAPF algorithm, it can be extended to MAPF by combining it with the Conflict-Based Search (CBS) algorithm. This fusion allows multiple agents to use A* to get to their respective goals while coordinating to avoid conflicts with one another (Fig. 3).
- One challenge with the solution in Fig. 3 is the sharp turns. These would be difficult for agents to execute, especially if they are drones. Instead, it is much easier for drones to follow rounded curves, which can be created using Bézier curves. This is essentially like “pulling” on the lines surrounding these sharp corners in different directions to form a smooth curve.
- Implementation of Bézier curves to “round” the paths formed by CBS is shown in Fig. 4.
- These methods were then tested in a more complex instance, with a larger environment and more agents (Fig. 5).

Skills Gained

- Reading and understanding scientific literature
- Capturing, analyzing, and presenting data
- Learning about the different systematic approaches to MAPF
- Understanding derivation and methods behind Bézier curves
- Effectively creating and using classes in Python
- Using various data structures such as arrays, sets, queues, stacks, and more

Future Research

- Simulating a more continuous space that allows more direct trajectories
- Implementing obstacle avoidance and narrow corridor navigation
- Setting a preference for smaller changes in direction
- Incorporating physical properties and behaviors of real drones
- Adding efficiency metrics beyond path length, such as elevation gain
- Optimize growth of algorithm runtime, which is currently $\Theta(n^2)$

Runtime Analysis

I analyzed the relationship between the number of agents and the runtime by steadily increasing the number of agents from 2 to 10. For each set, I ran CBS fifty times and recorded the average runtime (Fig. 6). I used two SciKitLearn modules, PolynomialFeatures and LinearRegression, to find a line of best fit for this data (Fig. 7). A quadratic curve fit the data best, showing this is an $\Theta(n^2)$ algorithm.

# of Agents	Avg. Runtime (ms)
2	20.742
3	223.914
4	426.549
5	432.280
6	1838.574
7	2043.750
8	1844.476
9	3438.979
10	3644.972

Acknowledgements

I would like to thank Professor Nora Ayanian for welcoming me to the ACT Lab and giving me this learning opportunity. A big thank you to my mentor, Eric Ewing, for explaining MAPF theory and guiding me throughout this project. Finally, thank you to Dr. Katie Mills, Monica Lopez, Cassandra Jeon, and the rest of the SHINE team and cohort for making this such an enriching and fun-filled experience!
